

IMPROVED ESTIMATES FOR THE DISCRETE FOURIER RESTRICTION TO THE HIGHER DIMENSIONAL SPHERE

CIPRIAN DEMETER

ABSTRACT. We improve the exponent in Bourgain's estimate [3] for the discrete restriction to the n dimensional sphere, from $p = \frac{2(n+1)}{n-3}$ to $p = \frac{2n}{n-3}$, when $n \geq 6$.

1. INTRODUCTION

Let $n \geq 2$ and $\lambda \geq 1$ be two integers. Define $N = [\lambda^{1/2}] + 1$ and

$$\mathcal{F}_{n,\lambda} = \{\xi = (\xi_1, \dots, \xi_n) \in \mathbb{Z}^n : |\xi_1|^2 + \dots + |\xi_n|^2 = \lambda\}.$$

When $n = 2, 3, 4$ it is known that for each ϵ we have $|\mathcal{F}_{n,\lambda}| \lesssim N^{n-2+\epsilon}$, but the upper bound is only sharp for certain values of λ . For example $\mathcal{F}_{3,\lambda} = \emptyset$ when $\lambda = 4^a(8m+7)$ for $a, m \in \mathbb{N}$. On the other hand, if $n \geq 5$ we have a sharp estimate $|\mathcal{F}_{n,\lambda}| \sim N^{n-2}$, see [6]. Throughout the paper, the implicit bounds hidden in the symbol \lesssim will depend on ϵ, p, q and n , but never on N .

The discrete restriction (sometimes called extension) problem relative to the sphere is concerned with determining the order of growth in N of the numbers

$$M_{p,q,n}(\lambda) = \sup_{a_\xi \in \mathbb{C}} \frac{\|\sum_{\xi \in \mathcal{F}_{n,\lambda}} a_\xi e(\xi \cdot \mathbf{x})\|_{L^p(\mathbb{T}^n)}}{\|a_\xi\|_{l^q}}$$

for $1 \leq p, q \leq \infty$. We use the notation $e(z) = e^{2\pi iz}$. It is conjectured in [3], [2] that

Conjecture 1.1. *For each $n \geq 3$ and $\epsilon > 0$ we have*

$$M_{p,2,n}(\lambda) \lesssim N^{\frac{n-2}{2} - \frac{n}{p} + \epsilon}$$

for each $p \geq \frac{2n}{n-2}$

Bourgain proved this in [3] when $p \geq \frac{2(n+1)}{n-3}$ and $n \geq 4$. Here we improve his range to

Theorem 1.2. *Assume $n \geq 6$ and $p \geq \frac{2n}{n-3}$. Then for each $\epsilon > 0$ we have*

$$M_{p,2,n}(\lambda) \lesssim N^{\frac{n-2}{2} - \frac{n}{p} + \epsilon}.$$

We would like to thank Yi Hu for stimulating discussions and to Alexandru Zaharescu for pointing out the reference [9].

2. A BRIEF OVERVIEW OF THE KNOWN RESULTS AND METHODS

The literature on the discrete restriction to the sphere is very sparse, we are only aware of three relevant papers [2], [3], [4]. We start by making a few simple observations.

First, note that $M_{p,q,n}(\lambda)$ is monotone in both p and q and it is always at least 1. It is conjectured in [3] that for the critical index $p_c := \frac{2n}{n-2}$ one has

$$M_{p_c,2,n}(\lambda) \lesssim N^\epsilon. \quad (1)$$

We recall that the "continuous" analogue of (1), proved by Thomas and Stein, is the estimate

$$\|\widehat{fd\sigma}\|_{L^p(\mathbb{R}^n)} \lesssim \|f\|_{L^2(S^{n-1})}, \quad p \geq \frac{2(n+1)}{n-1}. \quad (2)$$

The discrepancy between the critical exponents $\frac{2n}{n-2}$ and $\frac{2(n+1)}{n-1}$ in the discrete and continuous settings can be at least naively explained by the fact that the discrete sphere has "holes". More precisely, $\mathcal{F}_{n,\lambda}$ has roughly N^{n-2} points, while a maximal 1 separated set on the sphere $\{\xi \in \mathbb{R}^n : |\xi|^2 = \lambda\}$ has roughly N^{n-1} points. However, this discrepancy is not present in the case of the paraboloid

$$\{\xi_n = \xi_1^2 + \dots + \xi_{n-1}^2 : -N \leq \xi_1, \dots, \xi_{n-1} \leq N\},$$

where it is conjectured that $p_c = \frac{2(n+1)}{n-1}$. See [4] for the best known estimate for the paraboloid.

The bound $|\mathcal{F}_{2,\lambda}| \lesssim N^\epsilon$ trivially implies $M_{p,q,n}(\lambda) \lesssim N^\epsilon$ when $n = 2$, for each p, q . However, (1) is open when $n \geq 3$.

On the other hand (1) is known for some range below the critical index. For example, the bound for the number of lattice points on ellipses and a simple counting argument can be easily used to derive the estimate $M_{4,2,3}(\lambda) \lesssim N^\epsilon$, see [4]. Also, Bourgain's recent result in [4] proves (1) for $p \leq \frac{2n}{n-1}$, $n \geq 2$.

Remarkably, the conjectured bound (1) implies that for $n \geq 5$ we can determine all the values $M_{p,q,n}(\lambda)$ within a factor of N^ϵ . This is in contrast with the continuous version of the restriction problem, where the $q = 2$ case is fully understood via the work of Thomas and Stein, but a whole range of other estimates remains open (and very difficult!). We prove below that (1) implies

Conjecture 2.1. *For each $\epsilon > 0$ we have*

$$M_{p,q,n} \sim N^\epsilon, \text{ if } 1 \leq p \leq p_{c,q} := \frac{q'p_c}{2} \text{ and } q \leq 2 \quad (3)$$

$$M_{p,q,n} \sim_{N^\epsilon} N^{\frac{(n-2)}{q'} - \frac{n}{p}}, \text{ if } p_{c,q} < p \text{ and } q \leq 2 \quad (4)$$

$$M_{p,q,n} \sim_{N^\epsilon} N^{(n-2)(\frac{1}{2} - \frac{1}{q})}, \text{ if } 1 \leq p \leq p_c \text{ and } q > 2 \quad (5)$$

$$M_{p,q,n} \sim_{N^\epsilon} N^{\frac{(n-2)}{q'} - \frac{n}{p}}, \text{ if } p_c < p \text{ and } q > 2 \quad (6)$$

Proof We first prove the upper bounds for $M_{p,q,n}$. Note the trivial estimate

$$M_{\infty,1,n} \leq 1.$$

This together with (1) implies (3), by interpolation. (4) follows from (3) and the immediate bound $M_{\infty,q,n} \leq N^{\frac{n-2}{q'}}$, via Hölder. To see (5), note that using (1) and Hölder

$$\begin{aligned} \left\| \sum_{\xi \in \mathcal{F}_{n,\lambda}} a_\xi e(\xi \cdot \mathbf{x}) \right\|_{L^p(\mathbb{T}^n)} &\leq \left\| \sum_{\xi \in \mathcal{F}_{n,\lambda}} a_\xi e(\xi \cdot \mathbf{x}) \right\|_{L^{p_c}(\mathbb{T}^n)} \\ &\lesssim N^\epsilon \|a_\xi\|_{l^2} \leq N^{(n-2)(\frac{1}{2}-\frac{1}{q})+\epsilon} \|a_\xi\|_{l^q} \end{aligned}$$

Finally, to get the upper bound in (6) note that

$$\begin{aligned} \left\| \sum_{\xi \in \mathcal{F}_{n,\lambda}} a_\xi e(\xi \cdot \mathbf{x}) \right\|_{L^p(\mathbb{T}^n)} &\lesssim M_{p,2,n} \|a_\xi\|_{l^2} \\ &\leq M_{p,2,n} N^{(n-2)(\frac{1}{2}-\frac{1}{q})} \|a_\xi\|_{l^q} \lesssim N^{\frac{(n-2)}{q'}-\frac{n}{p}+\epsilon} \|a_\xi\|_{l^q}, \end{aligned}$$

where the last inequality follows from (4) with $q = 2$.

It remains to prove the lower bounds. The one in (3) is trivial, by taking the singleton $a_\xi = \delta_{\xi_0}$. Then (4) and (6) follow by noticing that

$$K(\mathbf{x}) := \sum_{\xi \in \mathcal{F}_{n,\lambda}} e(\xi \cdot \mathbf{x})$$

satisfies $|K(\mathbf{x})| \gtrsim N^{n-2}$ when $|\mathbf{x}| \lesssim N^{-1}$. Thus $\|K\|_p \gtrsim N^{n-2-\frac{n}{p}}$, while $\|a_\xi\|_{l^q} = N^{\frac{n-2}{q}}$, for each $1 \leq p, q \leq \infty$.

To see (5), a standard randomization argument shows that given any $1 \leq p \leq \infty$ and $q > 2$, there exists $a_\xi \in \{-1, 1\}$ such that

$$\left\| \sum_{\xi \in \mathcal{F}_{n,\lambda}} a_\xi e(\xi \cdot \mathbf{x}) \right\|_{L^p(\mathbb{T}^n)} \gtrsim \|a_\xi\|_{l^2} = |\mathcal{F}_{n,\lambda}|^{\frac{1}{2}-\frac{1}{q}} \|a_\xi\|_{l^q}.$$

■

An immediate corollary is that (1) implies Conjecture 1.1.

To prove Theorem 1.2 we apply the point of view from [7] on the Thomas-Stein restriction argument. This amounts to cutting the kernel in only two pieces, near rationals with denominators greater than N . The first piece is small in L^∞ norm. The second piece is supported in frequency away from the sphere, and its Fourier transform is small in the L^∞ norm. This type of construction has a lot of flexibility and in particular allows us to simplify the argument by working with prime moduli.

We will rely on three type of level set estimates corresponding to three different regimes. On the one hand, we use the sharp bounds for the Kloosterman and Salié sums, following the approach in [3]. Second we rely on a sharp estimate for certain partial moments of the Weyl sums. The third ingredient is the subcritical estimate in [4]. We mention the remarkable fact that the estimate in [4] does not rely at all on Number Theory, it is entirely of Fourier analytic flavor. See a brief account in Section 5.

The methods used in this paper seem to be insufficient to prove the conjectured optimal estimate for any $p > p_c$, when $n = 3, 4, 5$, but can be easily modified to recover the result in [3] for $n = 5$. It seems that further progress on the problem would require substantially new insight. One such possible avenue is getting estimates for moments of Kloosterman sums. This is briefly described in the end of the paper. See also [2].

3. SOME NUMBER THEORETICAL GENERALITIES

Let $1_{[-1,1]} \leq \gamma \leq 1_{[-2,2]}$ be a Schwartz function. Define the smooth Weyl sums

$$G(t, x) = \sum_{k \in \mathbb{Z}} \gamma(k/N) e(kx + k^2 t).$$

Inserting the smooth cut off will be completely harmless, in fact it will ease some of our computations. Let $t = \frac{a}{q} + \varphi$ where $(a, q) = 1$ and $|\varphi| < \frac{1}{q}$. Using the representation $k = rq + k_1$, $0 \leq k_1 \leq q-1$ and the Poisson summation formula we get

$$\begin{aligned} G(t, x) &= \sum_{k_1=0}^{q-1} e(k_1^2 a/q) \sum_{r \in \mathbb{Z}} \gamma\left(\frac{k_1 + rq}{N}\right) e((rq + k_1)x + (rq + k_1)^2 \varphi) \\ &= \sum_{m \in \mathbb{Z}} \left[\frac{1}{q} \sum_{k_1=0}^{q-1} e(k_1^2 a/q - k_1 m/q) \right] \left[\int_{\mathbb{R}} \gamma(y/N) e\left((x + \frac{m}{q})y + \varphi y^2\right) dy \right] \\ &= \sum_{m \in \mathbb{Z}} S(a, m, q) J(x, \varphi, m, q) \end{aligned} \tag{7}$$

where

$$\begin{aligned} S(a, m, q) &= \frac{1}{q} \sum_{k=0}^{q-1} e(k^2 a/q - km/q) \\ J(x, \varphi, m, q) &= \int_{\mathbb{R}} \gamma(y/N) e\left((x + \frac{m}{q})y + \varphi y^2\right) dy. \end{aligned}$$

Assume now that $2 \leq q \leq N$, and $|\varphi| \leq \frac{1}{Nq}$. The relevance of this choice is that, according to Dirichlet's theorem every $t \in [0, 1]$ is of the form $t = \frac{a}{q} + \varphi$, with $2 \leq q \leq N$ and $|\varphi| \leq \frac{1}{Nq}$. The classical van der Corput estimate reads

$$\left| \int_{\mathbb{R}} \gamma(z) e(Az + Bz^2) dz \right| \lesssim |B|^{-1/2},$$

and combining this with the trivial estimate we get

$$|J(x, \varphi, m, q)| \lesssim \min\{N, |\varphi|^{-1/2}\}.$$

On the other hand, repeated integration by parts shows that for each M and ϵ

$$|J(x, \varphi, m, q)| \lesssim_{M, \epsilon} N^{-M}$$

when $|xq - m| \geq N^\epsilon$. These values of m will produce a negligible contribution. Combining this with the classical estimate

$$|S(a, m, q)| \lesssim \frac{1}{\sqrt{q}}$$

we get

$$|G(t, x)| \lesssim_\epsilon \frac{N^\epsilon}{\sqrt{q}} \min\{N, |t - \frac{a}{q}|^{-1/2}\}. \tag{8}$$

We will also need more refined estimates for $S(a, m, q)$, in particular we will need to exploit cancelations when summing over a . We start by a simple computation. If q is odd then

$$\begin{aligned} S(a, m, q) &= e(-4^* a^*) \frac{1}{q} \sum_{k=0}^{q-1} e(a/q(k^2 - 2k2^* a^* m + 4^* (a^*)^2 m^2)) = \\ &= e(-4^* a^* m^2/q) \frac{1}{q} \sum_{k=0}^{q-1} e(k^2 a/q) = e(-4^* a^* m^2/q) \left(\frac{a}{q}\right) G(q). \end{aligned}$$

Here and in the following, x^* denotes the inverse of x modulo q , $(\frac{a}{q})$ is the Jacobi symbol, while

$$G(q) = \frac{1}{q} \sum_{k=0}^{q-1} e(k^2/q),$$

is the standard Gauss sum.

Fix m_j . Consider the function

$$\Sigma(s) = \sum_{(a,s)=1} \left[\prod_{j=1}^n S(a, m_j, s) e(-\lambda a/s) \right].$$

When $m_j = 0$ for each j , Σ becomes the classical singular series introduced by Hardy and Littlewood in the problem of representations of integers as sums of squares. See for example [6] for a detailed discussion.

It is easily seen that Σ is multiplicative, though we will not need to exploit this in our argument. Moreover, the previous computations show that for each odd q we have

$$\Sigma(q) = G(q)^n \sum_{(a,q)=1} \left(\frac{a}{q}\right)^n e\left(-\frac{4^* \tilde{m}^2 a^*}{q} - \lambda \frac{a}{q}\right)$$

where $\tilde{m} = m_1^2 + \dots + m_n^2$.

At this point we need to recall the Salié sums, for odd q

$$K_2(a, b, q) = \sum_{(k,q)=1} \left(\frac{k}{q}\right) e\left(\frac{ka}{q} + \frac{k^* b}{q}\right).$$

If q is a prime number, they have a remarkably simple formula, see for example [8]

$$K_2(a, b, q) = 2q \cos\left(\frac{4\pi x}{q}\right) G(q),$$

where $x^2 \equiv ab \pmod{q}$. In particular, we have

$$|K_2(a, b, q)| \leq 2\sqrt{q}$$

for each prime q .

Finally, recall the Kloosterman sums

$$K(a, b, q) = \sum_{(k,q)=1} e\left(\frac{ka}{q} + \frac{k^* b}{q}\right),$$

and their estimates for prime q

$$|K(a, b, q)| \lesssim q^\epsilon \sqrt{q} \sqrt{\gcd(a, b, q)}.$$

We conclude that for each q prime and for each n (both even and odd) we have

$$|\Sigma(q)| \lesssim q^\epsilon (\sqrt{q})^{1-n} \sqrt{(\lambda, q)}.$$

4. THE NEW LEVEL SET ESTIMATES

If $g : \mathbb{R}^n \rightarrow \mathbb{C}$ and $h : \mathbb{T}^n \rightarrow \mathbb{C}$, we will denote by $\widehat{g} : \mathbb{R}^n \rightarrow \mathbb{C}$ and $\mathcal{F}(h) : \mathbb{Z}^n \rightarrow \mathbb{C}$ their Fourier transforms.

For $\mathbf{x} \in \mathbb{T}^n$ recall that $K(\mathbf{x}) = \sum_{\xi \in \mathcal{F}_{n,\lambda}} e(\xi \cdot \mathbf{x})$. The integral points on the sphere do not have an explicit formula, we need to introduce a new variable t to fix this deficiency and we notice that

$$K(\mathbf{x}) = \int_{[0,1]} \prod_{j=1}^n \left[\sum_k \gamma(k/N) e(kx_j + k^2 t) \right] e(-\lambda t) dt \quad (9)$$

The kernel K is the discrete analogue of $\widehat{d\sigma}$, where $d\sigma$ is the surface measure on the sphere S^{n-1} in \mathbb{R}^n .

We now proceed with decomposing K in two pieces. For $N \leq Q \leq N^2$ define

$$A_Q := \{Q \leq q \leq 2Q : q \text{ is prime}\},$$

so that $|A_Q| \sim Q(\log Q)^{-1}$. The reason we work with this restricted set of moduli is to simplify the analysis of the Kloosterman, Salié and Ramanujan sums. The cardinality N_Q of the set of Farrey fractions

$$F_Q := \left\{ \frac{a}{q} : q \in A_Q, 1 \leq a \leq q-1 \right\}$$

satisfies $N_Q \sim Q^2(\log Q)^{-1}$.

Let $0 \leq \eta \leq 1_{[-1,1]}$ be a Schwartz function. Define $c_Q = \frac{10Q^2 \int \eta}{N_Q}$ and

$$\eta_Q = c_Q \sum_{a/q \in F_Q} \eta((t - a/q)10Q^2).$$

Note that $\int \eta_Q = 1$ and $c_Q \lesssim \log Q$. Define also

$$K^Q(\mathbf{x}) = \int_{[0,1]} \prod_{j=1}^n G(t, x_j) e(-\lambda t) \eta_Q(t) dt.$$

We will prove the following

Proposition 4.1. *Given $N \leq Q \leq N^2$ we have for each $n \geq 1$ and ϵ*

$$\|K^Q\|_\infty \lesssim Q^{\frac{n-1}{2} + \epsilon}$$

Proof Fix $q \in A_Q$, $|\varphi| \leq (10Q^2)^{-1}$ and $\mathbf{x} \in \mathbb{T}^n$. Since φ is small, the trivial estimate prevails over the van der Corput one and the best we can say is

$$|J(x_j, \varphi, m, q)| \lesssim N.$$

Repeated integration by parts shows as before that

$$|J(x_j, \varphi, m, q)| \lesssim_{M,\epsilon} N^{-M}$$

if $|x_j + \frac{m}{q}| > N^{-1+\epsilon}$, for each $\epsilon, M > 0$. This means that in the summation (7) the range of values of m can be restricted to an interval $I_{x_j, q}$ of length $O(\frac{Q}{N^{1-\epsilon}})$, if error terms of order $O(N^{-M})$ are to be tolerated.

For each $(m_1, \dots, m_n) \in \prod I_{x_j, q}$ we have from the previous section that

$$\left| \sum_{(a, q)=1} \prod_{j=1}^n S(a, m_j, q) e(-\lambda a/q) \right| \lesssim q^\epsilon (\sqrt{q})^{1-n} \sqrt{(\lambda, q)},$$

for each $n \geq 1$. By invoking (7), summing over the $(Q/N^{1-\epsilon})^n$ values in $\prod I_{x_j, q}$, and integrating over $|\varphi| \lesssim (10Q^2)^{-1}$ we get for each $M > 0$

$$|K^Q(\mathbf{x})| \lesssim_{\epsilon, M} Q^{n-2+\epsilon} \sum_{q \in A_Q} q^\epsilon (\sqrt{q})^{1-n} \sqrt{(\lambda, q)} + N^{-M} \lesssim Q^{n-2} Q^\epsilon (\sqrt{Q})^{3-n} = Q^{\frac{n-1}{2}+\epsilon}.$$

We have used the fact that since $\lambda \leq Q^2$, there can be at most one $q \in A_Q$ such that $(\lambda, q) > 1$. \blacksquare

The estimate in the previous proposition is good for Q close to N . The next result is a much more elementary estimate which is good for large Q .

Proposition 4.2. *Given $N \leq Q \leq N^2$ we have for each $n \geq 4$*

$$\|K^Q\|_\infty \lesssim N^{2+\epsilon} Q^{\frac{n-4}{2}}$$

Proof Fix $x \in \mathbb{T}$ and $2^s \gtrsim N^\epsilon \sqrt{N}$. From (8) we deduce that

$$|\{t \in [0, 1] : |G(t, x)| \geq 2^s\}| \lesssim \sum_{q \lesssim (\frac{N^{1+\epsilon}}{2^s})^2} \frac{\phi(q)}{q 2^{2s}} \lesssim N^{2+2\epsilon} 2^{-4s},$$

where ϕ is the Euler totient function. The proof of Proposition 4.1 shows that on the support S_Q of η_Q we have

$$|G(t, x)| \lesssim N^\epsilon \sqrt{Q}.$$

Thus for each fixed x

$$\|G(t, x)\|_{L^n(S_Q)}^n \lesssim N^{2+\epsilon} \sum_{N^{\frac{1}{2}+\epsilon} \leq 2^s \lesssim N^\epsilon \sqrt{Q}} 2^{s(n-4)} + N^{\frac{n}{2}+\epsilon} \lesssim N^{2+\epsilon} Q^{\frac{n-4}{2}}.$$

The result now follows from Hölder in t and Fubini in the x_j variables. \blacksquare

To summarize, we have for each $n \geq 4$

$$\|K^Q\|_\infty \lesssim \begin{cases} N^2 Q^{\frac{n-4}{2}+\epsilon} & : \text{ if } Q \geq N^{4/3} \\ Q^{\frac{n-1}{2}+\epsilon} & : \text{ if } N \leq Q \leq N^{4/3} \end{cases}. \quad (10)$$

We also have the following estimate on the Fourier side

Proposition 4.3. *Given $N \leq Q \leq N^2$ we have for each $n \geq 1$*

$$\|\mathcal{F}(K - K^Q)\|_\infty \lesssim N^\epsilon Q^{-1}.$$

Proof Note that for each $\mathbf{k} \in \mathbb{Z}^n$

$$\mathcal{F}(K - K^Q)(\mathbf{k}) = \widehat{1 - \eta_Q}(|\mathbf{k}|^2 - \lambda) \prod_{i=1}^n \gamma\left(\frac{k_i}{N}\right).$$

If l is any nonzero integer then

$$\begin{aligned} \widehat{1 - \eta_Q}(l) &= c_Q(10Q^2)^{-1} \widehat{\eta}\left(\frac{l}{10Q^2}\right) \sum_{q \in A_Q} \sum_{a=1}^{q-1} e(la/q) \\ &= c_Q(10Q^2)^{-1} \widehat{\eta}\left(\frac{l}{10Q^2}\right) \sum_{q \in A_Q} \sum_{a=1}^{q-1} e(la/q) \\ &= c_Q(10Q^2)^{-1} \widehat{\eta}\left(\frac{l}{10Q^2}\right) \left(\sum_{q \in A_Q: q \text{ divides } l} q - |A_Q| \right). \end{aligned}$$

When l gets larger, the increase of the number of its prime divisors from A_Q is offset by the decay of $\mathcal{F}(\eta)$, and we get

$$|\widehat{1 - \eta_Q}(l)| \lesssim_\epsilon Q^{\epsilon-1}.$$

The result now follows from the fact that $1 - \eta_Q$ has mean zero. ■

Assume now $\|a_\xi\|_{l^2(\mathcal{F}_{n,\lambda})} = 1$ and let

$$F(\mathbf{x}) = \sum_{\xi \in \mathcal{F}_{n,\lambda}} a_\xi e(\xi \cdot \mathbf{x}).$$

For $\alpha > 0$ define

$$\begin{aligned} E_\alpha &= \{\mathbf{x} \in \mathbb{T}^n : |F(\mathbf{x})| > \alpha\}, \\ f(\mathbf{x}) &= \frac{F(\mathbf{x})}{|F(\mathbf{x})|} 1_{E_\alpha}(\mathbf{x}). \end{aligned}$$

It follows that

$$\alpha |E_\alpha| \leq \int_{\mathbb{T}^n} \bar{F}(\mathbf{x}) f(\mathbf{x}) d\mathbf{x} = \sum_{\xi \in \mathcal{F}_{n,\lambda}} \bar{a}_\xi \mathcal{F}(f)(\xi),$$

and thus

$$\alpha^2 |E_\alpha|^2 \leq \sum_{\xi \in \mathcal{F}_{n,\lambda}} |\mathcal{F}(f)(\xi)|^2 = \langle K * f, f \rangle.$$

This in turns implies that

$$\alpha^2 |E_\alpha|^2 \leq \|K^Q\|_\infty |E_\alpha|^2 + \|\mathcal{F}(K - K^Q)\|_\infty |E_\alpha|.$$

We now use (10), by choosing Q appropriately so that the upper bound for $\|K^Q\|_\infty$ is roughly α^2 . We get for each $n \geq 5$

$$|E_\alpha| \lesssim \begin{cases} N^{\epsilon \frac{1}{2 \frac{n+1}{n-1}}} & : \text{ if } N^{\frac{n-1}{4}} \leq \alpha \leq N^{\frac{n-1}{3}} \\ N^{\frac{4}{n-4} + \epsilon} \frac{1}{\alpha^{\frac{1}{n-4}}} & : \text{ if } \alpha \geq N^{\frac{n-1}{3}} \end{cases}. \quad (11)$$

5. FROM CONTINUOUS TO DISCRETE RESTRICTION

One may wonder whether the estimate (2) for some p directly implies its discrete analogue, namely $M_{p,2,n}(\lambda) \lesssim N^\epsilon$. The answer is "no" for both the sphere and the paraboloid, and here is why. It is a basic fact that (2) is equivalent with (B_N is the ball centered at the origin with radius N in \mathbb{R}^n)

$$\left\| \sum_{\xi \in \Lambda} a_\xi e(\xi \cdot \mathbf{x}) \right\|_{L^p(B_1)} \lesssim N^{\frac{n-1}{2} - \frac{n}{p}} \|a_\xi\|_{l^2(\Lambda)}$$

for each $a_\xi \in \mathbb{C}$ and each 1-separated set Λ on the sphere $\{\xi \in \mathbb{R}^n : |\xi|^2 = \lambda\}$. The result also holds for the paraboloid

$$\{\xi = (\xi_1, \dots, \xi_n) \in \mathbb{R}^n : |\xi_1|, \dots, |\xi_{n-1}| \leq N, \xi_n = \xi_1^2 + \dots + \xi_{n-1}^2\}.$$

Since (2) fails for $p = \frac{2n}{n-1}$, no valuable information can be derived this way about $M_{\frac{2n}{n-1},2,n}(\lambda)$. Luckily, the index $\frac{2n}{n-1}$ plays a key role in the multilinear restriction theory. More precisely, it was proved in [1] that if P_1, \dots, P_n are transverse regions of the sphere S^{n-1} (or the paraboloid), then one can improve over the Thomas-Stein exponent, at the expense of losing N^ϵ

$$\|(\Pi_{i=1}^n \widehat{f d\sigma_{P_i}})^{1/n}\|_{L^{\frac{2n}{n-1}}(B_N)} \lesssim N^\epsilon \|f\|_{L^2(S^{n-1})}.$$

As in the linear case, this implies

$$\|(\Pi_{i=1}^n |\sum_{\xi \in \Lambda_i} a_\xi e(\xi \cdot \mathbf{x})|)^{1/n}\|_{L^{\frac{2n}{n-1}}(B_1)} \lesssim N^\epsilon \|a_\xi\|_{l^2(\Lambda)}$$

where Λ is as before, while Λ_i are transverse subsets of Λ . This is the starting point in Bourgain's argument [4] which combines it with induction on scales to prove that, if Λ is in addition assumed to be in \mathbb{Z}^n , we have the unrestricted inequality

$$\left\| \sum_{\xi \in \Lambda} a_\xi e(\xi \cdot \mathbf{x}) \right\|_{L^{\frac{2n}{n-1}}(\mathbb{T}^n)} \lesssim N^\epsilon \|a_\xi\|_{l^2(\Lambda)}.$$

In particular,

$$M_{\frac{2n}{n-1},2,n}(\lambda) \lesssim N^\epsilon. \quad (12)$$

6. PROOF OF THEOREM 1.2

We use the notation from the previous section, and the assumption $\|a_\xi\|_{l^2(\mathcal{F}_{n,\lambda})} = 1$. Define the index $p_n = \frac{2n}{n-3}$. Bourgain's estimate (12) implies

$$|E_\alpha| \lesssim N^\epsilon \frac{1}{\alpha^{\frac{n}{2n-1}}},$$

valid for each $\alpha > 0$ and $n \geq 2$. Using this, we get the conjectured bound for each $n \geq 4$ and $p \geq p_n$ for α small

$$\int_0^{N^{\frac{n-1}{4}}} \alpha^{p-1} |E_\alpha| d\alpha \lesssim N^{p(\frac{n-2}{2} - \frac{n}{p} + \epsilon)}.$$

Using the bounds in (11) we get

$$\int_{N^{\frac{n-1}{4}}}^{N^{\frac{n-1}{3}}} \alpha^{p-1} |E_\alpha| d\alpha \lesssim N^{p(\frac{n-2}{2} - \frac{n}{p} + \epsilon)},$$

for $n \geq 6$ and $p \geq p_n$, and also

$$\int_{N^{\frac{n-1}{3}}}^{N^{\frac{n-2}{2}}} \alpha^{p-1} |E_\alpha| d\alpha \lesssim N^{p(\frac{n-2}{2} - \frac{n}{p} + \epsilon)},$$

for each $n \geq 5$ and all $p \geq 1$. This completes the proof.

7. CLOSING REMARKS

Improving further the range in Theorem 1.2 may rely on exploiting cancelations occurring in sums of Kloosterman sums. Such an example is the Selberg conjecture, which states that

$$\left| \sum_{q \leq X} \frac{K(m, n, q)}{q} \right| \lesssim (mnX)^\epsilon.$$

Since the typical size of $|K(m, n, q)|$ is \sqrt{q} , the conjecture predicts a square root cancellation between Kloosterman sums. Recent progress in this direction appears in [9] and [5].

The piece K^Q of the kernel K introduced earlier in the paper can be defined to incorporate all moduli $Q \leq q \leq 2Q$ (not only the primes), and the bound in Proposition 4.3 will continue to hold. It is possible that the correct bound for such a variant of K^Q to be

$$\|K^Q\|_\infty \lesssim Q^{\frac{n-2}{2}}. \quad (13)$$

This amounts to an additional square root cancellation over the result in Proposition 4.1. If (13) held true, the approach described in this paper would imply precisely the sharp level set estimate

$$|E_\alpha| \leq \frac{1}{\alpha^{\frac{2n}{n-2}}},$$

albeit only for $\alpha \gtrsim N^{\frac{n-2}{4}}$. The difficulty of getting the estimate

$$|K^Q(\mathbf{x})| \lesssim Q^{\frac{n-2}{2}}$$

for a fixed \mathbf{x} comes from the fact that while one of the entries m, n in the Kloosterman sum is fixed (it equals $-\lambda$), the other entry is variable, it depends on q .
